### The bootstrap for sampling distributions

### Assessing assumptions

- Our t-tests assume normality of variable being tested
- but, Central Limit Theorem says that normality matters less if sample is "large"
- in practice "approximate normality" is enough, but how do we assess whether what we have is normal enough?
- so far, use histogram/boxplot and make a call, allowing for sample size.

## What actually has to be normal

- is: sampling distribution of sample mean
- the distribution of sample mean over all possible samples
- but we only have one sample!
- Idea: assume our sample is representative of the population, and draw samples from our sample (!), with replacement.
- This gives an idea of what different samples from the population might look like.
- Called bootstrap, after expression "to pull yourself up by your own bootstraps".

3/22

### Blue Jays attendances

```
jays$attendance
    [1] 48414 17264 15086 14433 21397 34743 44794 14184
##
##
        15606 18581 19217 21519 21312 30430 42917 42419
   [17] 29306 15062 16402 19014 21195 33086 37929 15168
   [25] 17276
  A bootstrap sample:
 <- sample(jays$attendance, replace = TRUE)
S
    [1] 21195 34743 21312 44794 16402 19014 34743 21195
##
                    19014 19217 34743 19217 14433 15062
##
             18581
        16402 15062 34743 15062 15086 15168 15086 48414
   [25]
       30430
```

### Getting mean of bootstrap sample

- A bootstrap sample is same size as original, but contains repeated values (eg. 15062) and missing ones (42917).
- We need the mean of our bootstrap sample:

```
mean(s)
```

```
## [1] 23055.28
```

• This is a little different from the mean of our actual sample:

```
mean(jays$attendance)
```

```
## [1] 25070.16
```

- Want a sense of how the sample mean might vary, if we were able to take repeated samples from our population.
- Idea: take lots of bootstrap samples, and see how their sample means vary.

### Setting up bootstrap sampling

• Begin by setting up a dataframe that contains a row for each bootstrap sample. I usually call this column sim. Do just 4 to get the idea:

### Drawing the bootstrap samples

 Then set up to work one row at a time, and draw a bootstrap sample of the attendances in each row:

```
tibble(sim = 1:4) %>%
  rowwise() %>%
  mutate(sample = list(sample(jays$attendance, replace = TRUE)))
## # A tibble: 4 x 2
```

```
## sim sample
## <int> 1 <dbl [25]>
## 2 2 <dbl [25]>
## 3 3 <dbl [25]>
## 4 4 <dbl [25]>
```

• Each row of our dataframe contains *all* of a bootstrap sample of 25 observations drawn with replacement from the attendances.

### Sample means

• Find the mean of each sample:

```
tibble(sim = 1:4) %>%
  rowwise() %>%
  mutate(sample = list(sample(jays$attendance, replace = TRUE))) %>%
  mutate(my_mean = mean(sample))
```

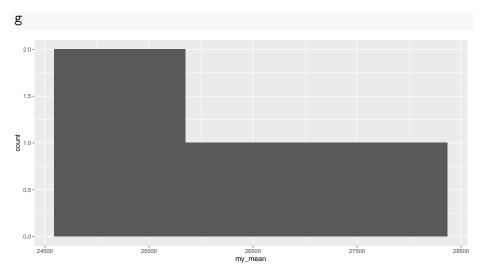

• These are (four simulated values of) the bootstrapped sampling distribution of the sample mean.

### Make a histogram of them

• rather pointless here, but to get the idea:

```
tibble(sim = 1:4) %>%
  rowwise() %>%
  mutate(sample = list(sample(jays$attendance, replace = TRUE))) %>%
  mutate(my_mean = mean(sample)) %>%
  ggplot(aes(x = my_mean)) + geom_histogram(bins = 3) -> g
```

# The (pointless) histogram

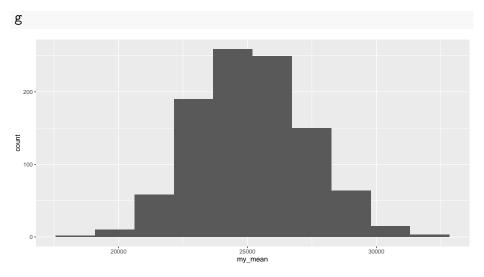

### Now do again with a decent number of bootstrap samples

• say 1000, and put a decent number of bins on the histogram also:

```
tibble(sim = 1:1000) %>%
  rowwise() %>%
  mutate(sample = list(sample(jays$attendance, replace = TRUE))) %>%
  mutate(my_mean = mean(sample)) %>%
  ggplot(aes(x = my_mean)) + geom_histogram(bins = 10) -> g
```

# The (better) histogram

#### Comments

- This is very close to normal
- The bootstrap says that the sampling distribution of the sample mean is close to normal, even though the distribution of the data is not
- A sample size of 25 is big enough to overcome the skewness that we saw
- This is the Central Limit Theorem in practice
- It is surprisingly powerful.
- Thus, the *t*-test is actually perfectly good here.

#### Comments on the code

You might have been wondering about this:

```
tibble(sim = 1:4) %>%
  rowwise() %>%
  mutate(sample = list(sample(jays$attendance, replace = TRUE)))
```

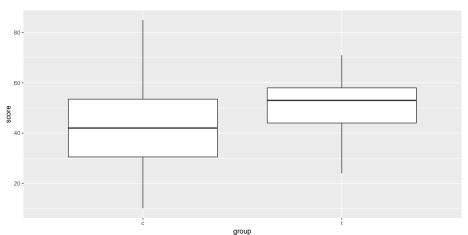

- how did we squeeze all 25 sample values into one cell?
  - sample is a so-called "list-column" that can contain anything.
- why did we have to put list() around the sample()?
  - because sample produces a collection of numbers, not just a single one
  - the list() signals this: "make a list-column of samples".

### Two samples

- Assumption: both samples are from a normal distribution.
- In practice, each sample is "normal enough" given its sample size, since Central Limit Theorem will help.
- Use bootstrap on each group independently, as above.

### Kids learning to read

### Getting just the control group

Use filter to select rows where something is true:

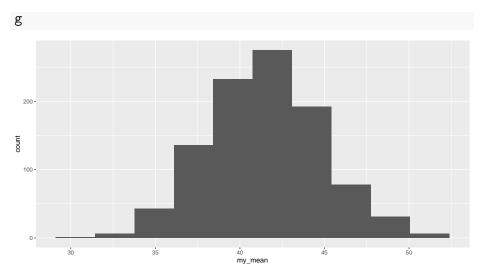

```
kids %>% filter(group=="c") -> controls
controls
```

```
## # A tibble: 23 x 2
## group score
##
  <chr> <dbl>
## 1 c
              42
              33
## 2 c
## 3 c
              46
  4 c
             37
##
##
  5 c
              43
              41
##
   6 c
##
  7 c
              10
              42
##
   8 c
   9 c
              55
##
```

### Bootstrap these

```
tibble(sim = 1:1000) %>%
  rowwise() %>%
  mutate(sample = list(sample(controls$score, replace = TRUE))) %>%
  mutate(my_mean = mean(sample)) %>%
  ggplot(aes(x = my_mean)) + geom_histogram(bins = 10) -> g
```

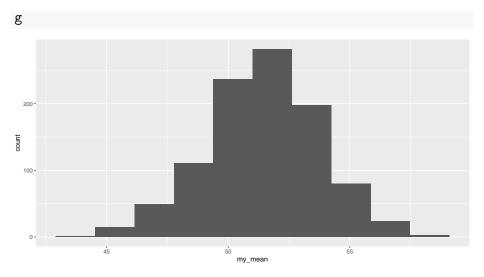

### Plot

### ... and the treatment group:

```
kids %>% filter(group=="t") -> treats
tibble(sim = 1:1000) %>%
   rowwise() %>%
   mutate(sample = list(sample(treats$score, replace = TRUE))) %>%
   mutate(my_mean = mean(sample)) %>%
   ggplot(aes(x = my_mean)) + geom_histogram(bins = 10) -> g
```

## Histogram

#### Comments

- sampling distributions of sample means both look pretty normal
- ullet as we thought, no problems with our two-sample t at all.
